Start-up Components

We are the experts in constant-fill and fill-controlled hydrodynamic soft-start couplings within Voith Turbo.

Voith Turbo, the specialist for hydrodynamic drive, coupling and braking systems for road, rail and industrial applications, as well as for ship propulsion systems, is a Group Division of Voith GmbH.

Voith sets standards in the markets energy, oil & gas, paper, raw materials and transportation & automotive. Founded in 1867, Voith employs almost 40 000 people, generates Euro 5.2 billion in sales, operates in about 50 countries around the world and is today one of the biggest family-owned companies in Europe.

Formula symbols

The formula symbols used generally correspond to DIN 1304 or typical international use. To improve readability and ensure quick comprehension, there are additional explanations for some formula symbols at points.

1 Dawn of the hydrodynamic power transmission

Fig. 1: Prof. Hermann Föttinger
(b. February 9, 1877 in Nuremberg [DE];
d. April 28, 1945 in Berlin [DE])

The development of hydrodynamic power transmission goes back to a basic patent filed by young electrical engineer Dr. Hermann Föttinger in the year 1905. As an employee of a shipyard (Stettiner Vulkan), it was his task to combine the quickly running steam turbine (drive machine) emerging in the ship-building industry with the slow running ship's propeller (driven machine). The steam turbine provided significantly improved efficiency compared with the directly coupled piston steam engine used up to that point. It was also more powerful and required less space.

Essentially, Föttinger had to solve two problems:

1. Converting the torque (T) and speed (ω)
2. Reversing the direction of the propeller for forward-/reverse travel

Föttinger's first idea was a direct conversion using a gear unit. This idea was quickly discarded because the gears at that time were only sufficiently resistant to a force of 500 HP.
Fig. 2: Föttinger's sketch of the idea of hydrodynamic power conversion. The pump and turbine are still physically separate.
Fig. 3: A cross-section of the drive system for the trial ship he built (constructed in 1909).
From right to left: Steam turbine, converter for reverse travel, converter for forward travel, outgoing propeller shaft.

Another idea was indirect electrical conversion using a rotating differential transformer. However, the high-voltage equipment that would be required for this on-board and the large mass and considerable volume meant that this solution was not an option.

Systematic and purely theoretical problem-solving studies finally brought Föttinger to hydrodynamics. He developed the hydrodynamic torque converter (the Föttinger converter), a true feat of engineering that gave him an extremely efficient method of converting the power factors between the driving and driven machinery.

In recognition of his pioneering work in the field of hydrodynamics, Föttinger was offered a chair as professor of fluidics at the Technical University in Danzig in 1909, and at the Technical University in Berlin in 1924.

2 Drive systems
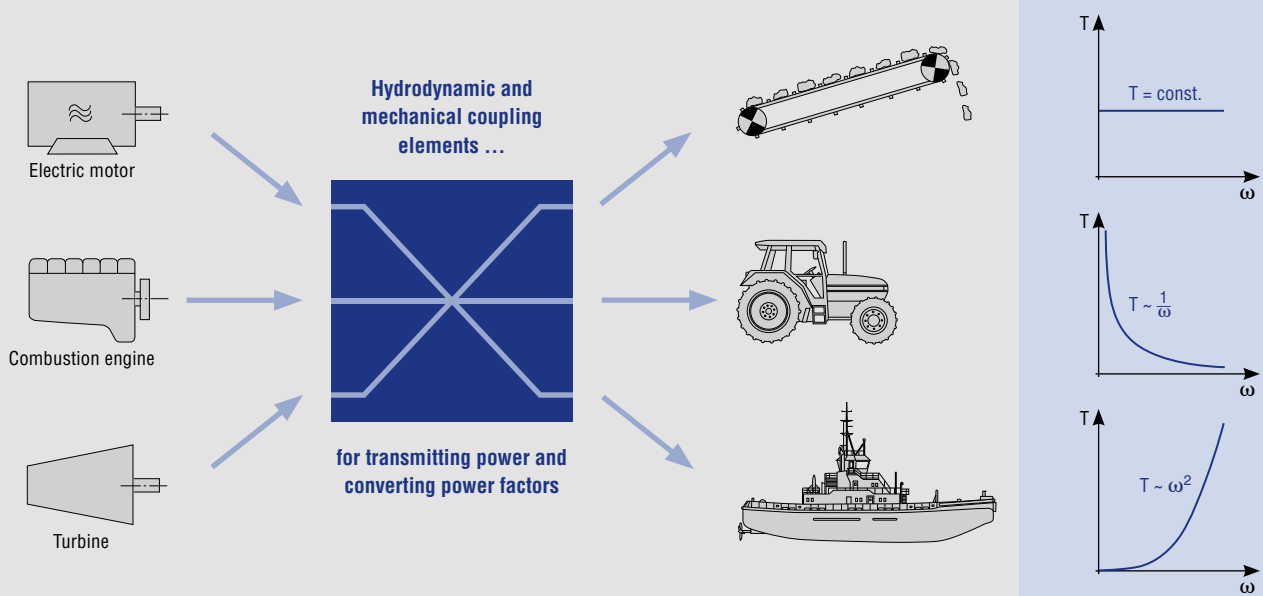

Fig. 4: Power transmission elements combine the driving machine with the driven machine.

The value of industrial drive systems increases with the value of the functions made available by the respective drive for the driven machine or process. It is therefore essential for the drive engineer to understand the driven processes and their requirements.

The same questions must be answered for today's drive and driven machinery as for those in use 100 years ago:

- Which drive system is required for the process?
- What kind of drive machinery can serve the process?
- What types of drive machinery are available?
- Which features of drive or driven machinery are not applicable to the process? What technical drive elements are suitable for adaptation?

    hydrodynamic energy

Fig. 5: Power transmission and conversion according to the indirect operating principle

2.1 The operating principles of hydrodynamic power transmission

Transmitting power from the driver to the driven machine occurs predominantly according to the **direct operating principle** in conventional machine construction, for example through shafts, mechanical couplings or gear units. Despite the great variety of gear units used to convert the torque and speed through gears, belt pulleys etc., their operating mechanisms all lead back to the lever or wedge.

In contrast, hydrodynamic power transmission occurs based on an **indirect operating principle.** A primary part (pump wheel) transfers the introduced mechanical energy to kinetic energy in fluid flow. The higher energy fluid flows centrifically from the pump wheel to the secondary part (turbine wheel), where a reconversion to mechanical energy (force) takes place. The power is transferred from the pump to the turbine without any contact, and thus without wear. Only the required bearing and sealing elements are subject to natural wear and tear.

Another advantage of the indirect torque transmission principle is the difference in transfer behavior between steady state and fluctuating torque conditions. Primary or secondary low-frequency torque fluctuations are severely dampened during the transfer; higher-frequency torque fluctuations are barely passed on at all. The inertia and friction behavior of the rotating fluid flow are the reasons for this characteristic.
Fig. 6: Principle of hydrodynamic power transmission. The pump and turbine become one unit, a hydrodynamic coupling in this case.

Hydrodynamic units contain primary and secondary-part flow machinery: a centrifugal pump and a turbine. The torque results from the directional flow change experienced by the rotating fluid in the respective vane wheels through deflection.

The vane wheels (pump impeller and turbine wheel) are arranged in an enclosed housing so that the fluid immediately flows through all wheels one after the other. The vane wheels do not come into contact with each other; only the fluid flow creates the torque transmission between the wheels. The turbine speed, or hydrodynamic slip, changes according to the load – a trait unique to hydrodynamic couplings. The pump impeller is connected to the primary driver, the turbine wheel to the driven machine.

2.2 Föttinger units

The method proposed by Föttinger for hydrodynamic power transmission led to three units:

- Hydrodynamic torque converter (converter)
- Hydrodynamic coupling (turbo coupling, flow coupling, fluid coupling)
- Hydrodynamic brake (retarder, flow brake)

In honor of Hermann Föttinger as their inventor, hydrodynamic power transmitters are also referred to as "Föttinger units."

The torque converter is the basic unit, with the coupling and brake being special cases. Directive VDI 2153 establishes the terms, designations, versions, principles of operation and calculation methods used.
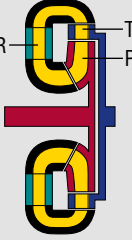

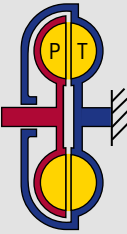

Föttinger unit	Basic elements	Description	Schematic representation	Symbolic representation	Main features
Converter		Hydrodynamic torque converters have at least three vane wheels (main parts) that redirect the flow: the pump, turbine and reaction member, also called a guide wheel.			$T_P + T_T + T_R = 0$ $\omega_P \geq \omega_T$ or $\omega_P < \omega_T$
Coupling		Hydrodynamic couplings have two vane wheels as main parts: the pump and turbine, which together with a shell form the working chamber.			$|T_P| = |T_T|$ $\omega_P > \omega_T$
Brake		Hydrodynamic brakes have one rotating and one fixed vane wheel: the pump (rotor) that is connected to the drive shaft, and the turbine (stator) that is connected to the housing.			$|T_P| = |T_T|$ $\omega_T = 0$

Fig. 7: Basic elements and main features of the Föttinger units. P: pump, T: turbine, R: reaction member (guide wheel).

3 Hydrodynamic principles

Fig. 8: Daniel Bernoulli
(b. February 8, 1700 in Groningen [NL];
d. March 17, 1782 in Basel [CH])
Fig. 9: Leonhard Euler
(b. April 15, 1707 in Basel [CH];
d. September 18, 1783 in St. Petersburg [RU])

3.1 Fluidic connections

Processes in hydrodynamic machines and installations can be described using the relationships of fluidics. The most important physical parameters are the speed, pressure, density and viscosity of flowing media. The media can be fluid or gaseous. Hydrodynamic power transmitters actually only use fluids, since only they offer a sufficiently high density.

Daniel Bernoulli and Leonhard Euler laid the foundations of fluidics in the 18th century. Building on **Bernoulli's energy equation**

$$g \cdot h + \frac{p}{\rho} + \frac{1}{2} \cdot c^2 = Y = \text{const.}$$

Euler developed **Euler's equation for turbomachinery** from the principle of linear momentum (Newton's second law):

$$Y = \Delta\left(r \cdot c_u\right) \cdot \omega = \Delta\left(u \cdot c_u\right) = \left(r_2 \cdot c_{u2} - r_1 \cdot c_{u1}\right) \cdot \omega$$
$$= u_2 \cdot c_{u2} - u_1 \cdot c_{u1}$$

Bernoulli's energy equation states that, in a stationary and friction-free flow, the sum of the energy forms "height, pressure and speed" remains constant. Height and pressure energy play only a subordinate role in flow machinery. It is the change of flow speed in both amount and direction between the inlet and outlet of the vane wheel that determines the torque at the machine shaft.

Euler's turbine equation describes these circumstances:

$$T = \dot{m} \cdot (r_2 \cdot c_{u2} - r_1 \cdot c_{u1})$$

From this, the transferred power can be calculated:

$$P = T \cdot \omega = \dot{m} \cdot (r_2 \cdot c_{u2} - r_1 \cdot c_{u1}) \cdot \omega = \dot{m} \cdot Y \,,$$

where Y is the specific hydrodynamic energy. In flow machinery, Y is designated as the enthalpy.

c : Absolute velocity	Indices legend:
u : Circumferential velocity	2 : Inlet
w : Relative velocity	1 : Outlet
	u : Circumferential component
	m : Meridian component

Fig. 10: Principle sketch clarifying Euler's turbine equation. The spin change is the difference ($r_2 \cdot c_{u2} - r_1 \cdot c_{u1}$).

3.2 Similarity laws for hydrodynamic power transmitters

Describing the torque characteristic of a hydro-dynamic power transmitter using Euler's turbine equation has proven to be too awkward in practice. The similitude and model laws for flow machinery provide a simplified representation that is more useful for practical situations.

3.2.1 Geometric similarity

Geometric similarity is an indispensable pre-requisite to be able to compare (test) models with real machines from smaller or larger series.

If there is geometric similarity, the following applies to all measurements in the three dimensions:

$$\frac{x_M}{x_P} = \frac{y_M}{y_P} = \frac{z_M}{z_P} = k = \text{const. ,}$$

where k is the scaling factor.

Transferred to flow machinery, this means that the same scale is applied to the geometry in all three directions in space.
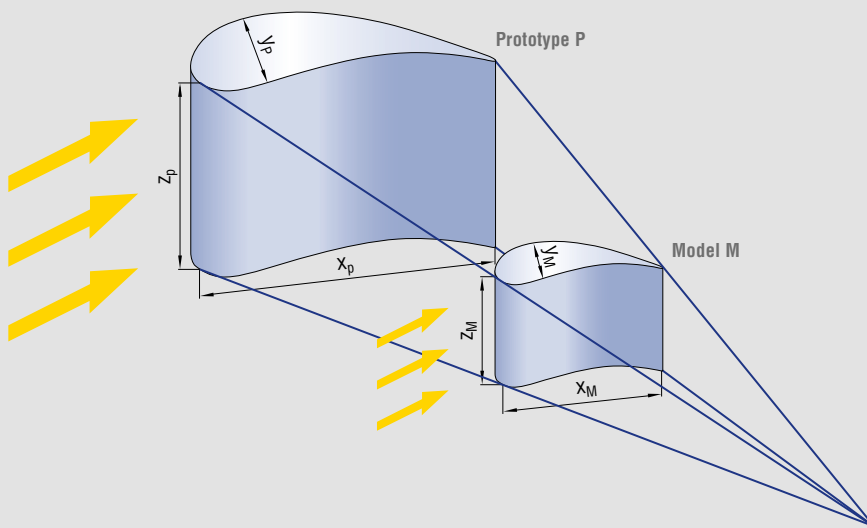

Fig. 11: Same length ratios, this means geometrically similar models

3.2.2 Similarity of flow velocities

The similarity of flow velocities is given where the velocity triangle is similar at analogous positions; this means their respective angles are the same or the size ratio of the respective sides is the same.

c : Absolute velocity

u : Circumferential velocity

w : Relative velocity

D_P : Profile diameter
Fig. 12: Geometric similarity and similarity of flow velocities using pump impellers as an example

3.2.3 Similarity of hydrodynamic power transmitters

Euler's turbine equation

$$T = \dot{m} \cdot (r_2 \cdot c_{u2} - r_1 \cdot c_{u1})$$
$$= \rho \cdot \dot{V} \cdot (r_2 \cdot c_{u2} - r_1 \cdot c_{u1})$$

contains geometric parameters (radii and flow surfaces), velocities and media density.

In addition to geometric similarity, complete application of the similarity and model laws requires similarity of fluid-element flow velocities at analogous positions for both model and reality.

Thus, the similarity relationships for hydrodynamic power transmitters listed in Fig. 13 apply.

Basic parameters of the hydrodynamic power transmitter	Designation	Similarity relationship
Length, radius, material thickness	l, r, s	$\sim D$
Surfaces, cross-sections	A	$\sim D^2$
Volumes, masses	V, m	$\sim D^3$
Velocities	c, u, w, v	$\sim \omega \cdot D$

Fig. 13: Similarity laws for hydrodynamic power transmitters

The similarity laws for hydrodynamic power transmitters are essentially fulfilled if the Euler number Eu and Reynolds number Re (Fig. 14) from the similarity theory of fluidics for models and real machines are the same.

Characteristic	Calculation	Relative strength
Euler number	$Eu = \dfrac{p}{\rho \cdot v^2}$	$\dfrac{\text{Compressive force}}{\text{Inertia force}}$
Reynolds number	$Re = \dfrac{v \cdot l}{\nu}$	$\dfrac{\text{Inertia force}}{\text{Frictional force}}$

Fig. 14: Dimensionless characteristics of fluidics

If you insert the similarity relationships (Fig. 13) into Euler's turbine equation, the following results:

$$T_P \sim \rho \cdot D_P^5 \cdot \omega_P^2 \quad \text{with}$$

T_P: Hydrodynamic torque of the pump
ρ: Density of the operating fluid
D_P: Profile diameter of the pump impeller, largest radial vane profile extension of the pump (possible deviating definition for torque converters)
ω_P: Angular velocity of the pump impeller

The proportionality factor is a dimensionless characteristic that directive VDI 2153 stipulates as binding for Föttinger units and describes as the λ power coefficient. λ describes the level of power take-up for geometrically and fluidically similar converters, couplings and brakes (same

Euler and Reynolds number) and considers design, fill level and other features. As such, the following equations apply to torque and power:

$$T_P = \lambda \cdot \rho \cdot D_P^5 \cdot \omega_P^2 \ ,$$

$$P_P = T_P \cdot \omega_P = \lambda \cdot \rho \cdot D_P^5 \cdot \omega_P^3$$

For other flow machines, for example pumps, turbines or fans, a proportionality factor can be derived from Euler's turbine equation in the same manner.

The model laws for hydrodynamic power transmitters presented in Fig. 15 are useful for practical situations.

Meaning	Equation	Model law	Proportionality factor	Use
Flow pressure	$Eu = \text{const.}$	$p \sim \rho \cdot D^2 \cdot \omega^2$	1	Calculation of pressures
Flow force	$F = \int p \cdot dA$	$F \sim \rho \cdot D^4 \cdot \omega^2$	Axial force factor δ (Voith internal)	Calculation of axial thrust
Volume flow	$\dot{V} = A \cdot c$	$\dot{V} \sim D^3 \cdot \omega$	Specific volume flow q (Voith internal)	Calculation of fluid flows for changing fill level and cooling
Mass flow	$\dot{m} = \rho \cdot \dot{V}$	$\dot{m} \sim \rho \cdot D^3 \cdot \omega$	Specific volume flow q (Voith internal)	Calculation of fluid flows for changing fill level and cooling
Torque	$T = F \cdot r$	$T \sim \rho \cdot D^5 \cdot \omega^2$	Power coefficient λ (VDI 2153)	Calculation of torque transmission
Power	$P = T \cdot \omega$	$P \sim \rho \cdot D^5 \cdot \omega^3$	Power coefficient λ (VDI 2153)	Calculation of power transmission

Fig. 15: Generally valid model laws for flow machines

3.3 Interaction of several flow machines

In Föttinger units, at least two flow machines work together (pump and turbine). The two wheels are exclusively coupled by flow forces (hydrodynamic torque transmission). The turbine speed is independently and continuously adjusted according to the load. This is a feature unique to hydrodynamic couplings.

In drive technology, dimensionless ratio values are used to describe this special characteristic:

Characteristic	Relationship		
Speed ratio	$\nu = \dfrac{\omega_T}{\omega_P} = \dfrac{n_T}{n_P} = 1 - s$	$\omega_P:$	Pump angle velocity
		$\omega_T:$	Turbine angle velocity
Slip [1]	$s = \dfrac{\omega_P - \omega_T}{\omega_P} = \dfrac{n_P - n_T}{n_P} = 1 - \nu$	$n_P:$	Pump speed
		$n_T:$	Turbine speed
Conversion (torque ratio)	$\mu = \left| \dfrac{T_T}{T_P} \right|$	$T_P:$	Pump torque
		$T_T:$	Turbine torque
Efficiency (power ratio)	$\eta = \dfrac{P_T}{P_P} = \dfrac{T_T \cdot \omega_T}{T_P \cdot \omega_P} = \mu \cdot \nu$	$P_P:$	Pump power
[1] The slip is typically given as a % : s = s · 100 %.		$P_T:$	Turbine power

Fig. 16: Dimensionless characteristics for flow machines

The dependence of the transmitted torque on the speed ratio ν is characterized as the **"first characteristic relationship"** of the Föttinger units. Naturally, the power coefficient λ for Föttinger units is not a constant, but rather dependent on the speed ratio ν:

$$\lambda = f(\nu)$$

In addition to the speed ratio, there are other parameters influencing the power coefficient: the layout and function of the vane wheels, the filling level of the Föttinger unit and other design features.

3.3.1 Primary characteristic curves

A **primary characteristic curve** describes the dependence of the pump torque T_P on the pump speed n_P (drive speed, primary speed) at constant speed ratio ν. Due to the laws of similarity, the primary characteristic curves represent parabolas that are indicated by a λ-value. For other speed ratios, other λ-values apply, and thus other parabolas. This set of curves results in the "**primary characteristic curves.**" In practice, the primary characteristic curves are also called slip parabolas.

Here:

$$T_P \sim n_P^2 \Big|_{\lambda,\,\nu\,=\,\text{const.}}$$

3.3.2 Secondary characteristic curves

A **secondary characteristic curve** (frequently just called a **characteristic curve**) describes the dependence of the power coefficient λ on the speed ratio ν with a constant drive speed n_P for torque converters and couplings. This dependence is called the "first characteristic relationship" (see 3.3) or the characteristic curve of the Föttinger units.

Here:

$$\lambda = \frac{T_P}{\rho \cdot D_P^5 \cdot \omega_P^2} = f(\nu)\Big|_{n_P,\,\omega_P\,=\,\text{const.}},$$
$$\lambda \sim T_P$$

Fig. 17: Primary characteristic curves of the three Föttinger units of the same size with typical design limits on the power coefficient λ and maximum pump speeds, related to the same profile diameter

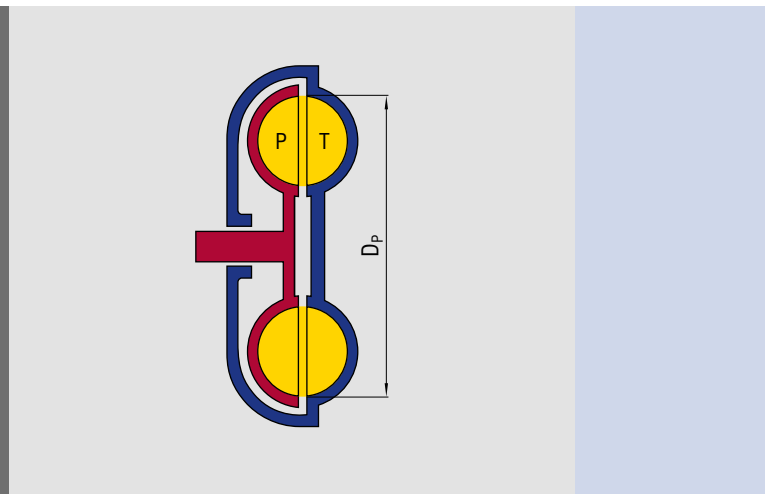

Fig. 18: Sketch of the profile diameter D_P
	Trilok converter	Föttinger converter (Lysholm converter)	Counter-rotation converter (DIWA converter)

Course of characteristic curve	Deviating at $\nu \approx 1$, zero crossing at $\nu = 1$	Almost constant	Increasing	
Turbine feature	Centripetal throughflow	Centrifugal throughflow	Axial throughflow	
Throughflow sequence	P → T → R		P → R → T	
Housing feature	Rotating	Fixed	Fixed	

Fig. 19: Secondary characteristic curves for various designs of torque converters and couplings

The course of a secondary characteristic curve, the course of the pump torque with increasing turbine speed at constant pump speed, is strongly dependent on the throughflow of the turbine in the circuit. In the case of a turbine with centripetal throughflow (from the outside inward, applying to all couplings and to Trilok converters depending on their function), the pressure drop between pump and turbine falls as the turbine speed increases. This reduces the circumferential mass flow required for transporting energy. Where $\nu = 1$ the drop in pressure is zero; the secondary characteristic curve has a zero crossing.

The classic Föttinger converter with centrifugal throughflow turbine (from the inside outward) behaves differently. Here the turbine hardly has hardly any effect on the power take-up of the pump. Axial throughflow converter turbines like the counter-rotation converter increase the capacity of the pump through increasing turbine speeds – essentially, it is fed.

Secondary characteristic curves (frequently just referred to as **characteristic curves**) result from changes to regulating variables such as guide vane position, throttle opening and filling that influence the spinning of the fluid elements and/or the circumferential mass flow. This makes it possible to transfer different torques at the same turbine speed n_T (secondary speed).

	Fluid coupling completely filled	Fluid coupling partially filled	Fluid coupling with retaining capacity RC completely filled
	$\left|T_P\right| = \left|T_T\right|, \quad \mu = \left|\dfrac{T_P}{T_T}\right| = 1$		
	Steadily falling		Self-formative The unvaned retaining capacity RC takes on part of the operating fluid when turbine speeds are low
	Centripetal throughflow		
	Rotating		

Converters are almost exclusively operated completely filled. This required a fill pressure (superimposing pressure) that prevents flow separations, and thus cavitation. Adjustable guide vanes (reaction member) create the secondary characteristic curves by changing the spin and mass flow.

Couplings are almost exclusively operated partially filled. Conducting or carrying off operating fluid while at a standstill or during operation changes the circumferential mass flow and creates the secondary characteristic curves.

3.4 Determining characteristic curves

The mathematical development of characteristic curves for hydrodynamic power transmitters has come a long way. Louis Henri Navier and George Gabriel Stokes laid the groundwork for this at the end of the 19th century. They described a transient, frictional flow field using a differential equation that can only be solved analytically in very simple cases.

The one-dimensional streamline flow theory provides a simplified approach to calculating characteristic curves. It enables the principle course of characteristic curves to be described in the case of completely filled Föttinger units. This calculation approach is rarely suitable for partially filled units, especially couplings.

In the 1970s, it became possible to describe the transient flow spectrum through suitable statistical turbulence models. This provided the breakthrough for numeric solution methods for the Navier-Stoke differential equation. The advances in computer technology with increasingly powerful computers now permit an efficient and true-to-reality simulation of flow problems. This process is known as "computational fluid dynamics" or CFD for short, and is today a fixed component in the development and design process of Föttinger units. The scope of the model attempts to determine characteristic curves is thus considerably reduced.

A final model or prototype test confirms the hydrodynamic design data and properties (characteristic curves). The power coefficient λ is calculated from the measured power factors.
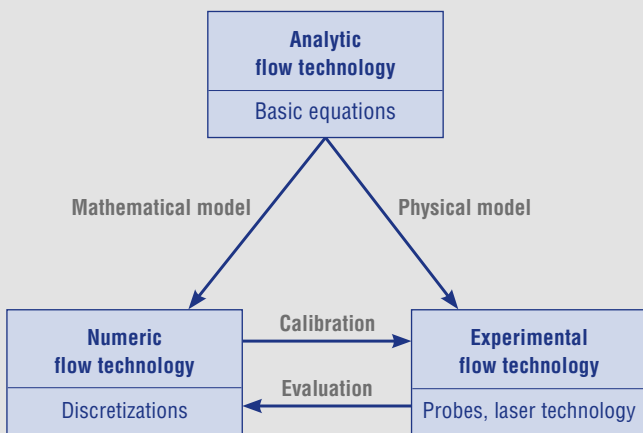

Fig. 20: Methods of fluidics
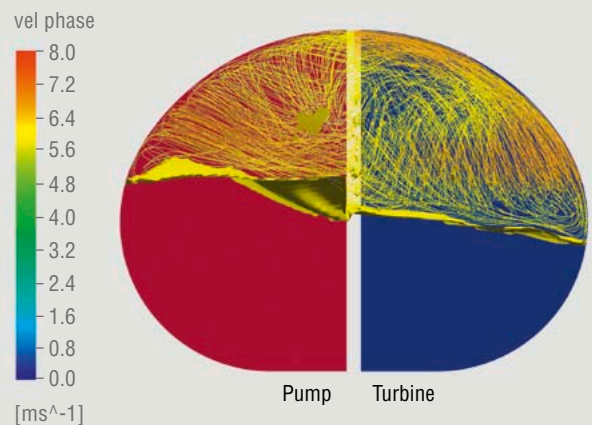

Fig. 21: CFD simulation of a partially filled Voith Turbo fluid coupling

4 Hydrodynamic couplings

Hydrodynamic couplings only contain two circumferential vane wheels (pump impeller and turbine wheel), frequently called the primary and secondary wheel in practice. Ignoring minimal loss moments from air friction or sealing elements, the hydrodynamic torques at both pump and turbine are the same. The operating fluid flows from the pump directly into the turbine and from the turbine back into the pump; there are no further elements on which a torque can be supported.

The following equations applies to **couplings**:

$$|T_P| = |T_T| \, ,$$

$$\mu = \left| \frac{T_T}{T_P} \right| = 1 \, ,$$

$$\eta = \frac{P_T}{P_P} = \frac{T_T \cdot \omega_T}{T_P \cdot \omega_P} = \mu \cdot \nu = \nu \quad \text{and}$$

$$\lambda = \frac{T_P}{\rho \cdot D_P^5 \cdot \omega_P^2} \quad \text{where} \quad \lambda \sim T_P, T_T \big|_{\omega_P = \text{const.}}$$
Fig. 22: 3-D sectioned model of a hydrodynamic constant-fill coupling with fluid distribution during start-up
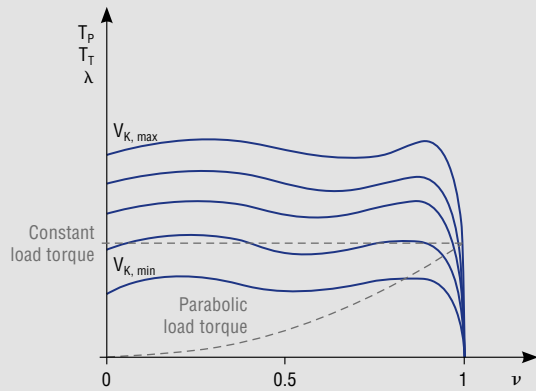

Fig. 23: Secondary characteristic curves of a soft-start and safety coupling
Fig. 24: Secondary characteristic curves of a variable-speed coupling and clutch coupling

4.1 Characteristic curves

The characteristic relationship $\lambda = f(\nu)$ in the form of a characteristic curve describes the transfer behavior of the coupling at constant drive speed (see 3.3.2). A set of characteristic curves results from the **fill level** V_K as a parameter, referred to as the (secondary) characteristic curves of a hydrodynamic coupling.

The characteristic curve basic form for hydrodynamic couplings has a strictly monotone falling course (see Fig. 19). The size selection corresponds to the featured principle of turbine speed adjustment so that the required rated torque (λ_N) is transferred with the lowest possible rated slip. Additional drive requirements determine the type of coupling and the associated course of the characteristic curve.

For **soft-start and safety couplings** that are constantly filled, a characteristic curve as horizontal as possible over the entire start-up range is usually best. This developed characteristic curve course provides driven machines with constant load torque (e.g. belt conveyors) for a near-constant acceleration torque and good limitation of maximum torque (λ_{max}).

For **variable-speed couplings and clutch couplings,** where the filling level actively changes during operation, steadily falling characteristic curves with a wide range are desirable. This results in stable operating points with drive speed control/adjustment, for both driven machines with parabolic load torque and driven machines with constant load torque.

Fig. 25: Voith Turbo fluid coupling in a belt conveyor drive

Fig. 26: Voith Turbo fluid coupling in a bucket-wheel excavator drive

4.2 Fluid couplings in drive systems

The complete description of drive systems with hydrodynamic couplings requires the view of the behavior with changing drive speed $n_P = f(t)$. Variable drive speeds are especially present during the start-up process. A load-dependent pressing of the drive motor or system-dependent speed fluctuations also cause variable drive speeds.

The load-dependent, independent setting of turbine speed (see 3.3) and the dependence of the transferrable torque from the square of the drive speed (see 3.3.1) leads to noteworthy advantages for the drive system (see 4.5).

The behavior with variable drive speed is of special significance for couplings with constant fill, since active change of the fill level during operation is not possible.
Fig. 27: Belt conveyor with hydrodynamic constant-fill coupling in the drives

4.2.1 Electric motor, multi-motor drives

The squirrel cage asynchronous (induction) motor is the most widely distributed electric motor today, especially in stationary drive technology. The main reasons for this are the low acquisition costs, low maintenance and the robust quality of the machine itself.

A disadvantage of the squirrel cage asynchronous motor is the high starting current. After connecting the stator voltage, a starting current flows when the motor is at a standstill that is 5 to 9 times the rated current, depending on the type of motor. This high starting current causes a drop in voltage, especially with weak power supply systems, which leads to a drop in motor torque in the end (proportional to the square of the voltage drop). In individual cases, a total failure of the power supply is even possible.

A fluid coupling in the drive chain relieves the motor significantly during run-up, because the transferrable torque (coupling torque) increases as a square function of the drive speed. The motor quickly runs through the high-current range, so the effects of voltage drops on the drive system are minimal.

With multi-motor drives and weak power supplies, it is easily possible to have time-delayed activation of the individual motors to protect the power supply. The fluid couplings in the first drives to be activated slip until the total system torque required to break free is achieved.
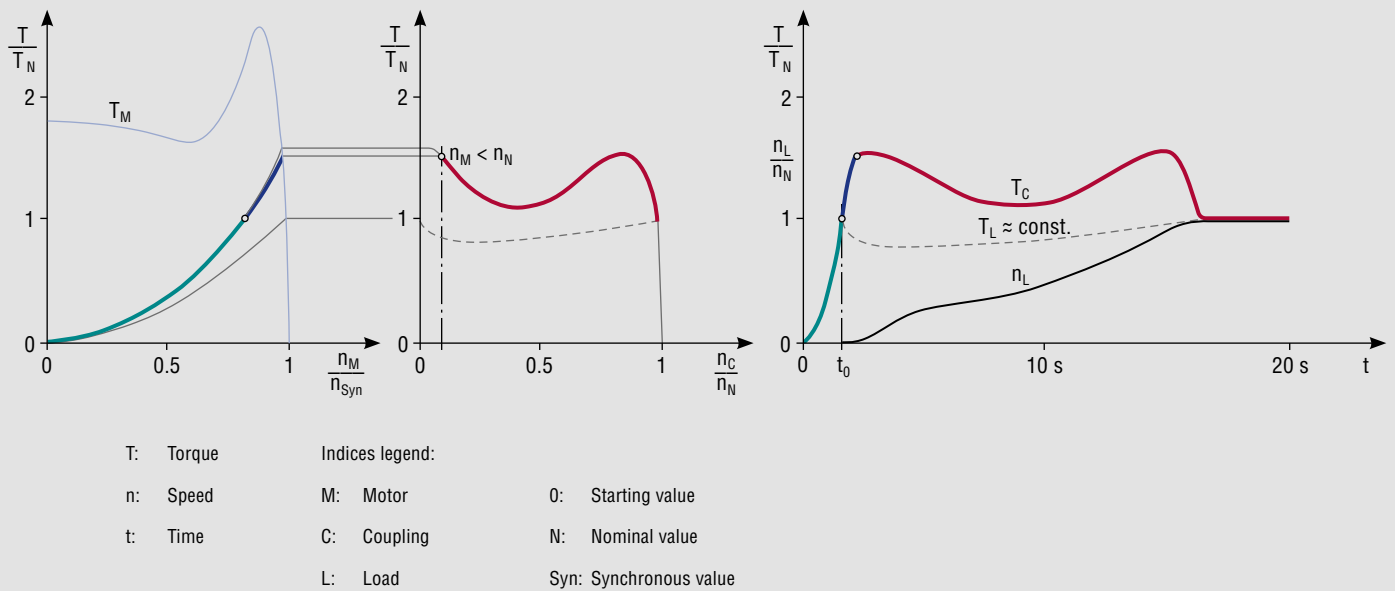

Fig. 28: Drive process of a loaded belt conveyor with hydrodynamic constant-fill coupling (type TVV) in the drive.
Left: *Primary characteristic curve and characteristic curve of a squirrel cage asynchronous (induction) motor;*
Center: *Secondary characteristic curve;* ***Right:*** *Torque and speed over time.*

Fig. 28 describes the start-up process of a typical belt conveyor with hydrodynamic constant-fill coupling in the drives.

Green: The hydrodynamic coupling largely de-couples the start-up process of the asynchronous electric motor and belt conveyor. Up to point in time t_0, a coupling moment T_C (turbine torque) builds up that increases parabolically with the motor speed n_M. The belt conveyor begins to move once the coupling torque T_C has exceeded the load torque T_L. At this point in time, the motor has not yet reached its final speed.

Blue: The coupling torque is also dependent on the speed ratio v with further increasing motor speed according to the secondary characteristic curve.

Red: After ending the motor run-up, the coupling torque corresponds to the secondary character-istic curve. The fluid coupling limits the introduc-ed torque in the conveyor very efficiently. The conveyor gently accelerates to its rated speed due to the excessive torque.
Fig. 29: Start-up of a belt conveyor drive with asynchronous electric motor and fluid coupling; the load torque is virtually constant

The characteristics necessary for calculating the start-up can be clearly presented in a diagram (Fig. 29). They are taken from the primary and secondary characteristic curves.

Fig. 30: Tractor with hydrodynamic constant-fill coupling in the drive chain

4.2.2 Diesel engine

The diesel engine with turbocharger is a very widely used combustion engine, especially in mobile drive technology. This engine type has an advantageous level of efficiency up to the partial load operating range. High reliability and a long service life contribute to its appeal.

Disadvantages of the diesel engine with turbo-charger include the lack of power at low speeds due to minimal load pressure (turbo lag), the engine stopping when it becomes overloaded (stalling) and the excitation of torsional vibrations in the drive chain.

A fluid coupling in the drive chain relieves the diesel engine so much that the engine can be started with a coupled drive. In the event of overload, the torque-limiting characteristic of the coupling prevents the engine from stalling. The fluid coupling very effectively dampens the tor-sional vibrations and torque peaks in the drive chain through its indirect operating principle.
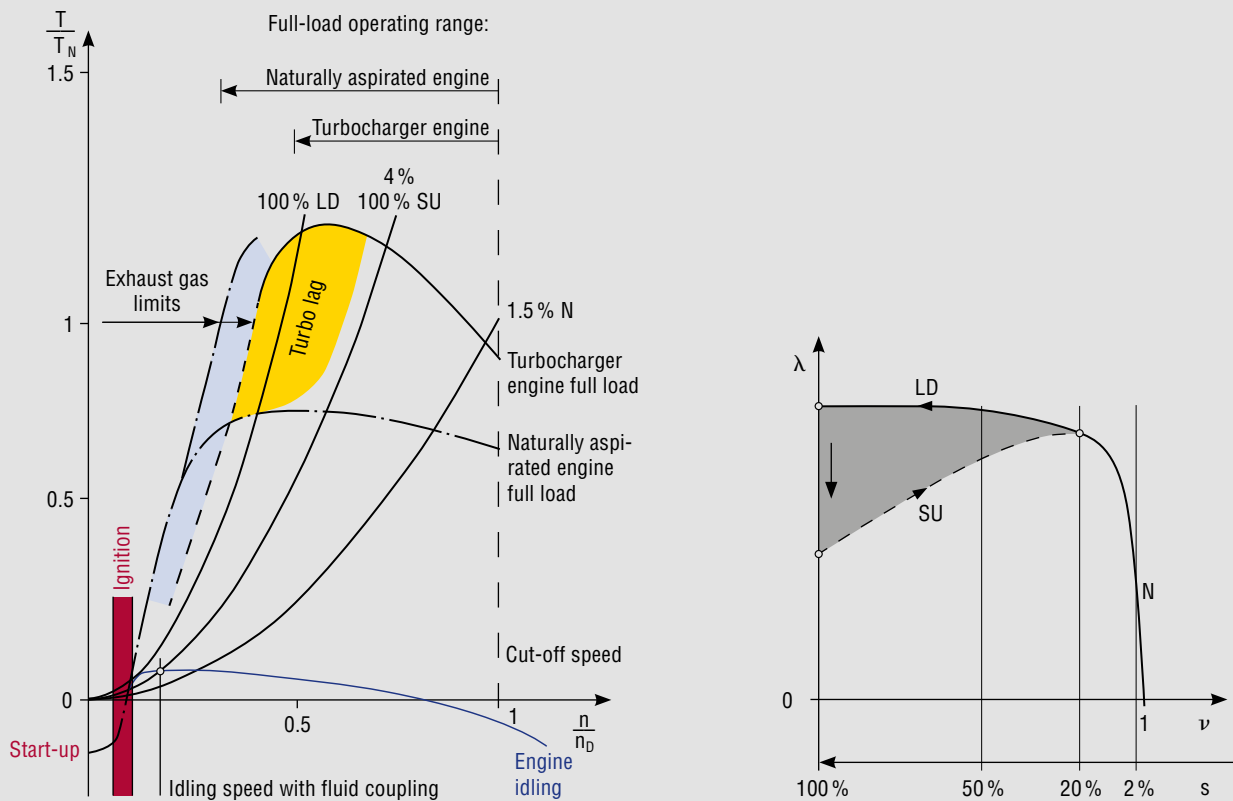

Fig. 31: Operational behavior of a tractor with hydrodynamic constant-fill coupling (type TD) in the drive.
Left: *Comparison of the characteristic curve of a naturally aspirated engine and a charged engine;*
Center: *Dynamic secondary characteristic curve (different characteristic curve courses with change in power flow direction);* ***Right:*** *Operating characteristic curves for engine and vehicle.*

Fig. 31 describes the start-up process of a tractor with hydrodynamic constant-fill coupling in the drive chain.

Higher-performance tractors almost exclusively use diesel engines with turbochargers. The full-load characteristic curve of these engines follows the upper speed range of a constant power characteristic.

After start-up and ignition, the engine begins to run up on a naturally aspirated engine characteristic curve. Due to more refined exhaust regulations, this limitation characteristic curve (exhaust gas limit) was shifted toward the right to higher speeds. In the run-up phase, the combustion process does not produce sufficient exhaust quantities to achieve the desired charge pressure. The turbocharger engine achieves the full-load characteristic curve only with a delay. This behavior is also called turbo lag.

A fluid coupling with specially developed (dynamic) characteristic curve in the drive chain avoids the turbo lag when the engine is running up:

The diagram legend:
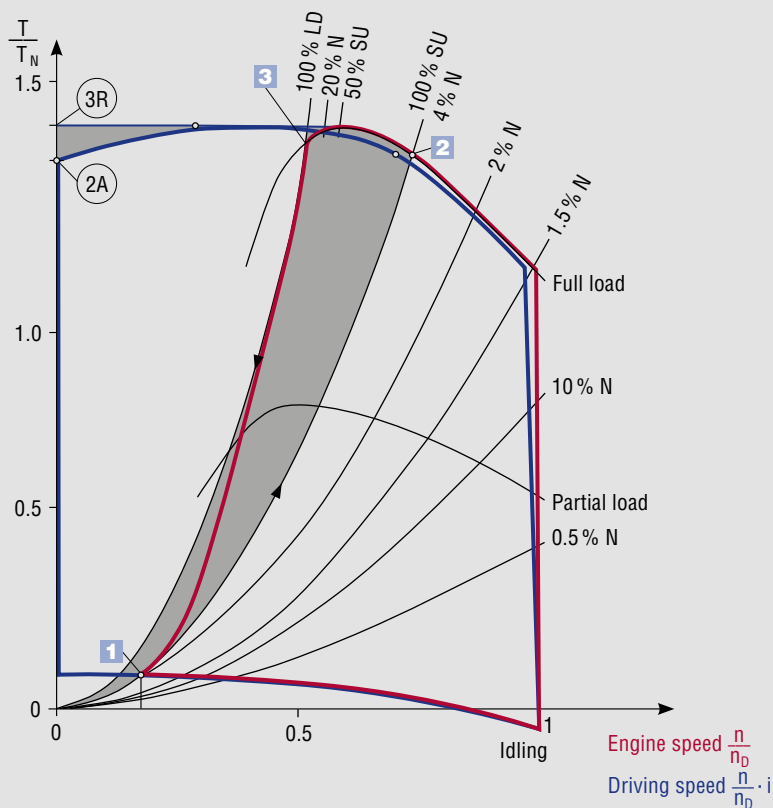

T : Torque

n : Speed

λ : Power coefficient

ν : Speed ratio

s : Slip

i : Gear

Indices legend:

N : Nominal value

D : Slow-down

Identification of the dynamic
characteristic curves:

SU : Start-up
(ν : 0 → 1)

LD : Load deceleration
(ν : 1 → 0)

N : Nominal operation
(ν : 0.8 − 1)

1 The section point of the coupling parabola "100 % A" with the standstill characteristic curve of the engine is selected so that a stable idling speed is set with coupled drive train. The coupling only transfers a minimal tractive torque (drag torque). The engine can be started when coupled.

2 When selecting the full-load operating point, the torque build up of the fluid coupling follows according to start-up characteristic curve "SU". This characteristic curve effectively bypasses the turbo lag. Nearly the maximum torque (2A) is available at a somewhat increased engine speed for vehicle acceleration. The vehicle gently and seamlessly accelerates to the rated speed.

3 When decelerating the engine out of nominal operation, the coupling loads the engine according to the load deceleration characteristic curve. The engine can be decelerated to a lower speed and completely utilize its characteristic curves, since a sufficient exhaust quantity is available for the turbocharger. The coupling characteristic curve (3R) prevents the engine from stalling, even when it is overloaded. The fluid coupling, with its 100 % slip parabola, limits the engine characteristic curves (red) differently for start-up and load deceleration. The operation of the vehicle (blue) can be seamlessly transferred from a standstill to nominal operation.

4.3 Dependence on rotation direction and direction of action

The preceding chapters describe the power transmission from pump impeller to turbine wheel in a specific rotation direction. However, various applications demand a view of the transmission behavior with reversal of the rotation direction and / or reversal of the direction of the power flow. In the latter case, the function of the vane wheels changes; the primary wheel takes on the function of the turbine and the secondary wheel the function of the pump.

An expansion of the secondary characteristic curves to four quadrants includes all conceivable operating conditions. Fig. 32 only shows the characteristic curves for an established rotation direction of the (electric) motor / generator to ensure a better overview. By mirroring the characteristic curves at the origin of the coordinate system, the characteristic curve course for the other rotation direction of the motor / generator results.

The 1st and 2nd quadrants describe the power flow from the primary to the secondary wheel with different rotation directions of the driven machine. In the 4th quadrant, the power flows from the driven machine to the motor / generator in the same rotation direction. The speed of the driven machine is higher than that of the generator.

The symmetrical design of the vane wheels and the hydrodynamic principle ensure the function for many coupling designs, regardless of the drive rotation direction. Most of the applications are limited to the operation in the 1st quadrant of the characteristic curves. The behavior in the remaining quadrants is of significance for special events or with special work processes.

Fig. 32: Stable characteristic curve course over three quadrants of the operating characteristic curves, presented for three rated speeds and one rotation direction of the drive motor.

Fig. 33: Coupling wheels with straight and diagonal vanes

Fig. 34: Marine propulsion with two diesel motors; the hydrodynamic coupling with diagonal vanes has good free-wheel action

The stable characteristic curve course in the 2nd quadrant allows, for example for marine propulsion, controlled braking of the propeller and turning of the propeller rotation direction.

The horizontal torque course around zero speed provides the opportunity, among other things, for a soft coil and tensioning mechanism for cables. The steep transition from 1st to the 4th quadrant enables a seamless change from motor to generator operation for electric motor drives. Such behavior is beneficial for belt conveyors partially or completely conveying downward, for example.

For standard designs, constructive solutions of pumps and other components can bind the operation to specific quadrants.

The pump impeller and turbine wheel for soft start and safety couplings generally have an asymmetric design (Fig. 19). This means there are different characteristic curve courses when there is a change in the power flow direction.

However, the transitions from the 1st to the 4th quadrant and vice versa are constant.

One special design is a coupling with vanes diagonal to the axle, also referred to as "inclined bladed wheels" (Fig. 33, right). This coupling variant has a distinct free-wheel action.

In marine propulsion where two diesel engines drive a propeller via a double gear unit, this behavior is particularly useful (Fig. 34): If, for example, engine 2 with n_2 drives the output side of coupling 1 faster than n_1 via the gear unit, then engine 1 only has minimal drag torque – even with a fully filled coupling. For variable-speed couplings and clutch couplings with coupling discharge, it is even possible to virtually decouple engine 1 from the traction of the drive. Afterwards, engine 1 can be shut down with no further action required.

4.4.1 Constant-fill couplings

Couplings of this design are mainly used for start-up, to limit torque and to influence the torsional vibration behavior of the drive chain.

The designs mainly differ through adjoining chambers, whose automatically controlled filling and emptying have a significant influence on the start-up behavior.

Constant-fill couplings are sealed to the outside. Filling first occurs before commissioning. Drive requirements determine the design and filling quantity. The ratio of the operating fluid volume filled to the overall volume of the coupling is called the fill level. The coupling obtains a specific characteristic curve from the fill level (see 4.1). Manually adding or removing operating fluid (at a standstill) enables subsequent characteristic curve adaptations.

4.4.2 Variable-speed couplings

Variable-speed couplings control or regulate the speed of the driven machine over a wide range below the drive speed. Stable operating points are set for the most important driven machine characteristic curves.

Variable-speed couplings have devices that seamlessly change the transmission behavior during operation. This mainly occurs by changing the fill level. Variable-speed couplings always have an external fluid circuit for filling changes that can also aid cooling.

The fill level can be changed during operation either via a radially movable scoop tube or by controlling the operating fluid inlet and outlet via valves and nozzles.

4.4.3 Clutch couplings

Clutch couplings simply interrupt the traction between the drive motor and driven machine by removing the operating fluid.

Clutch couplings have devices that change the transmission behavior during operation between two limit values (usually the maximum and minimum fill level). The known design principles for variable-speed couplings are particularly applied to clutch couplings.

4.5 Hydrodynamic features, advantages and benefits

Hydrodynamic couplings influence the power flow in a drive system in several ways through their operating principle. The required transmission features for torque and power as well as the influence on the entire system behavior are what determine the selection of a coupling in principle.

These transmission features are of significance for constant-fill couplings in particular, as they are at one with the operating principle with no external control intervention.

Fig. 36 compiles the most important hydrodynamic features of constant-fill couplings and indicates the resulting advantages and benefits for the entire system:

Hydrodynamic feature	Advantages, benefits
The coupling – and not the driven machine – determines the power output of the drive motor to the drive system	■ Load-free motor run-up ■ Gentle acceleration of the driven machine ■ No motor oversizing ■ Use of cost-effective standard motors
The coupling limits the maximum torque occurring in the drive chain in relation to speed	■ Overload and blocking protection ■ No oversizing of drive components ■ No drive-related oversizing of the driven machine ■ Protection and longer service life for all system components

System separation between the input and output side of the coupling, traction through flow of fluid	■ Wear-free transmission of power
	■ Minimum maintenance and repair costs
	■ For multi-motor drives:
	  – Time-delayed activation of motors to reduce load
	  – Improved load sharing

Damping and/or separation of torsional vibrations and torque peaks[1]	■ Improved dynamic features for the drive system and the system as a whole ■ Protection and longer service life for all system components
For constant-fill couplings only: Simple setting of transmission behavior by manually adding or removing operating fluid (at a standstill)	■ Subsequent operating adaptations are possible ■ Adjustable load sharing for multi-motor drives and no load oscillation
For variable-speed couplings only: Simple setting of transmission behavior by controlled adding or removing of operating fluid (during operation)	■ Control or regulation of start-up and operating process, adapted to the application ■ Controllable load sharing with multi-motor drives ■ Controlled emptying to interrupt the power flow in the drive chain
For clutch couplings only: Simple setting of transmission behavior by controlled adding or removing of operating fluid (during operation)	■ Controlled switching of power flow in the drive chain

[1] Primary or secondary low-frequency torque fluctuations are severely dampened during the transfer; higher-frequency torque fluctuations are barely passed on at all (see 2.1). This positive feature for the system can be described from a physical-mathematical perspective (Kelvin model).

Fig. 36: Advantages and benefits of Voith Turbo fluid couplings in the drive chain

The sum of advantages and benefits that the hydrodynamic power transmission simultaneously provides is unique. No other technology is able to offer this with such low expense and such simplicity!

5 The fluid coupling as a soft-start and safety coupling

Splitting the coupling designs in accordance with functional viewpoints in line with VDI 2153 into constant-fill couplings, variable-speed couplings and clutch couplings has not occurred in practice. Drive engineers generally prefer an application-oriented division into **soft-start and safety couplings** and **variable-speed couplings.**

Starting up drive systems and protecting the drive train against overload can in most cases be realized with constant-fill couplings. For more complex drive requirements, multiple fill-controlled couplings are used.

5.1 Fluid coupling with constant fill

Constant-fill fluid couplings are predominantly delivered "installation-ready" without operating fluid. Filling occurs at a standstill before commissioning. The requirements for start-up and transmission behavior determine the filling quantity (see 4.1).

Fig. 37: 3-D section model of a fluid coupling with constant fill (with operating fluid)
Fig. 38: Type T fluid coupling with elastic connection coupling for coaxial installation,
basic design of all fluid couplings with constant fill

The Voith Turbo fluid coupling in its simplest form (type T) consists of just a few main components without additional adjoining storage chambers. Together with the shell, the vaned outer wheel forms the working chamber that is housed relative to the hub and sealed outside. The inner part consists of the hub and the inner wheel, which are fixed together. To offset minimal assembly imprecision, a connection coupling is required in the shaft line in coaxial arrangement.

The constructive design of this basic format does not yet establish the function of the vaned wheels as pump or turbine. The functional establishment occurs through clear assembly instructions or through various bores of the hubs on the driving and output ends. The designation of the vaned

wheels is neutral and selected according to their position: inner wheel and outer wheel.

The power transmission is ensured with both installation variants,
1. Drive via outer wheel: **outer wheel drive** and
2. Drive via inner wheel: **inner wheel drive**.
However, dependent on the profile form, different characteristic curve courses form. Specially developed wheel profiles, mainly for inner wheels, lead to specific characteristic curves determined by the requirements. The coupling design establishes the type of drive (inner/outer wheel drive). A subsequent change requires a new check, especially with regard to torque limitation and heat dissipation.

Fig. 39: Design features for achieving a multifunctional type range

Voith Turbo has drawn on decades of experience to develop a multifunctional, modular type range for constant-filled fluid couplings. It is based on few main components and control features. This modular concept can fulfill a variety of requirements for the start-up and operating behavior as needed. The use of adjoining chambers and the volume exchange capability via fixed bores or bores closed with centrifugal force valves enable a great variation of characteristic curves in relation to speed, time and slip.

Voith type designation	Design features	Function description
T	Basic design	The working chamber filling determines the start-up and operating behavior.
T V	Normal delay chamber	The delay chamber takes in part of the operating fluid at a standstill.
T V V	Enlarged delay chamber	During start-up, the delay chamber empties into the working chamber via nozzle bores.
T V…S	Delay chamber and annular chamber	The delay chamber and annular chamber take in part of the operating fluid at a standstill. During motor run-up, the annular chamber also takes part of the operating fluid from the working chamber. During start-up, the delay chamber empties into the working chamber via nozzle bores.
T V…Y	Delay chamber and refill bores	The delay chamber takes in part of the operating fluid at a standstill. During motor run-up and at high slip, the working chamber partially empties into the delay chamber via the refill bores. With decreasing slip (increasing driven machine speed), the refilling process comes to a standstill. The delay chamber empties into the working chamber via nozzle bores.
T V…F	Delay chamber and centrifugal force valves	The delay chamber takes in part of the operating fluid at a standstill. During motor run-up and at high slip, the delay chamber continues to fill with operating fluid from the working chamber via the refill bores if the centrifugal force valves are open. Shortly before reaching motor rated speed (upper switching speed), the centrifugal force valves close and the refilling process comes to a stop. The delay chamber empties into the working chamber via nozzle bores. If weak power supplies have voltage drops with motor pressing, the centrifugal force valves open at a lower switch speed. The working chamber partially empties into the delay chamber via the refill bores. The load on the motor is relieved and it runs up again. This cyclic operation is repeated until the power supply is stabilized or a thermal fuse in the system responds.

Fig. 40: Design features for achieving a multifunctional type range
Fig. 41: Distribution of the operating fluid in a type TVVS fluid coupling.
1: Standstill; 2: Start-up; 3: Nominal operation.

A further element of the modular type range is the double circuit coupling version (Fig. 42, type DT). The two flow circuits of a DT coupling are switched parallel in principle. This enables double the power transmission with the same outer diameter. Function characteristics vary only insignificantly.

5.1.3 Selection criteria and hydrodynamic features

Power characteristic curves

As a rule, constant-fill couplings from the Voith modular type range use the same main components. This is especially true for the pump impeller and turbine wheel. As a result, one single set of power characteristic curves applies to all variants – assuming the same operating fluid (same density) is used.

The power of the driven machine and the rated speed of the drive motor are essential design factors for the coupling. They primarily determine the coupling size. The profile diameter is specified as a parameter in the power characteristic curves. The size graduation corresponds to a power jump of 2:1 with justifiable minimum slip values.

Since $P_P \sim D_P^5 \big|_{\omega_P = \text{const.}}$ (see 3.2.3), there is a progressive ratio of $1 : \sqrt[5]{2}$.

Fig. 43: Power characteristic curves for Voith Turbo fluid couplings with constant-fill *(operating fluid: mineral oil)*

The material strength of the main coupling parts determines the maximum permitted speed.

After an initial estimated determination of the coupling size from the power data, the use conditions determine the design and variant.

Finally, a check of the thermal load of the coupling is required. Generally, at least half of the start-up energy of each start-up process with slip must be converted into heat. The heat storage capacity and the amount of heat dissipation are therefore significant factors in the selection of the correct soft-start coupling.

Characteristic curves

The various coupling designs differ significantly in their characteristic curves (see 4.1), which have a substantial effect on determining the start-up behavior. For the majority of applications couplings with time-dependent characteristic curves (see 5.1.2) are sufficient.

5.1.4 TurboSyn – the fluid coupling with synchronization

For the start-up process of a drive system (heavy or loaded start-up), the special properties of the hydrodynamic power transmission are indispensable. For drive systems that do not require load sharing in continuous operation and for which damping of torsional vibrations and torque peaks is not necessary, the system-dependent slip can be omitted. The TurboSyn coupling provides this behavior – a constant-fill coupling with integrated synchronization. In nominal operation, it eliminates the slip between the pump impeller and turbine wheel by producing a friction-engaging connection between both wheels. The essential system properties of hydrodynamics remain virtually uninfluenced during the start-up process.

The basic design of the TurboSyn is very similar to a typical fluid coupling. Only the inner wheel (turbine wheel) consists of individual segments that are fastened pivoting to the hub eccentrically. Partial friction liners are applied to the outer surfaces of the inner wheel segments.

Fig. 45: Principle design of the TurboSyn coupling

Fig. 46: 3-D section model of a TurboSyn coupling

The start-up process begins hydrodynamically. The speed difference between the input and output side – the slip – decreases as the output speed increases. A force component from the torque presses the segments toward the hub. As the turbine speed increases, the centrifugal forces acting on the segments increase. At a specific speed ($\nu \approx 0.7$) these centrifugal forces prevail and bring the segments outward with increasing force at the shell to the system. A gentle transition occurs from the hydrodynamic power transmission into a slip-free frictional contact.

Application characteristics of the TurboSyn coupling:

- Maximum protection of the driven machine with heavy load and soft start
- The masses to accelerate only have a minimal influence on the synchronization device
- No torque transmission reduction
- An overload of the driven machine leads to opening of the synchronization device and transition to hydrodynamic torque transmission; the maximum transmittable torque is limited
- The control of the synchronization device occurs automatically with no outside intervention.

a + b: Total torque transmission

Fig. 47: Start-up characteristic curve of a constant-fill coupling with integrated synchronization, type TurboSyn

5.2 Fill-controlled fluid couplings

The integration of this type of coupling design into a drive system can vary significantly. In the simplest case, the scope of delivery only includes the pump impeller and turbine wheel as well as the surrounding shell; the operating fluid supply and its control is part of the overall system. With more complex requirements, self-supported coupling units with integrated operating fluid supply, cooling, monitoring and system control are used.

5.2.1 Basic design features

Fill-controlled fluid couplings are primarily supplied pre-assembled. The rotating parts, housing parts and the operating fluid supply are integrated into the drive system on-site. Fig. 48 and Fig. 49 show externally supported and self-supported couplings, executed as single and double circuit coupling with control principles "TP" and "TPK".

Control principle TP:
A fill pump delivers the operating fluid from a reservoir into the coupling. At the same time, operating fluid exits the coupling via nozzles in the shell into the housing. The control of transmission behavior occurs by coordinating the inlet volume flow with the outlet volume flow. The (working) chamber, formed by the pump impeller and shell, rotates in line with the motor speed. The fill level in this rotating chamber generates a rotation pressure and thus an outlet volume flow, dependent on the diameter of the nozzles in the shell. An increase of the inlet volume flow creates a higher fill level in the working chamber, which results in a higher torque transmission capability. The opposite also applies. In any case, the maximum pump delivery must be greater than the outlet volume flow with completely filled coupling. Overflow bores in the inner area of the shell

provide a fill limit. A start-up process is controlled or regulated via the adaptation of the inlet volume flow.

Control principle TPK:
This principle rests on the metered filling of the rotating working chamber. Here also, operating fluid exits the working chamber via nozzles, but in this case into an annular shell connected to the pump impeller. A dynamic pressure pump (fixed scoop tube) siphons off the operating fluid from this annular shell and then conducts it through a heat exchanger via a catching ring back into the working chamber. An outer, enclosed operating fluid circuit results. Working chamber filling changes indirectly through the addition or removal of operating fluid from this outer circuit. The flow rate of the filling pump only depends on the desired fill time of the working chamber. Advantages of the TPK principle are a high level of control accuracy, small operating fluid pumps and a higher overall efficiency than that of the TP principle.
*Fig. 48: Fill-controlled fluid coupling, type TP, externally supported, double circuit coupling*

Fig. 49: Fill-controlled fluid coupling, type TPKL, self-supported, single circuit coupling

5.2.2 Application-oriented type range

The varying integration depth of the fill-controlled couplings in the drive systems requires a very flexible type range design and scope of delivery. However, there is a trend toward compact, self-supported designs with integrated operating fluid supply.

Design features	Standard variants	Comments
Control principle	TP	Single system, but lower control accuracy
	TPK	High control accuracy and good overall efficiency
Number of flow circuits	Single circuit coupling	Minimal installation length
	Double circuit coupling	Power transmission twice as high as that of a single circuit coupling with the same outer diameter; mostly balanced axial forces
Operating medium	Mineral oil	Good resistance to cavitation and corrosion
	Water	Non-flammable, environmentally friendly operating fluid
Component scope	Pump impeller, turbine wheel and shell	Flexible integration in a closed drive chain
	Pump impeller, turbine wheel, shell and housing	Integration in a modular drive system
	Coupling with housing bearing at driving and output ends	Independent unit
	Coupling with housing bearing on either drive or output end	Mounting unit
Operating fluid supply	External	Component in drive chain
	Separate with cooler	Modular design
	Integrated in housing with cooler	Completely independent unit
Control/regulation	External	–
	Only fill control and monitoring	–
	System control, regulation and monitoring	–

Fig. 50: Features of the application-oriented type range of fill-controlled fluid couplings

The main components of the fill-controlled fluid couplings are derived from the variable-speed coupling series. Essentially, this is the profile form of the vane wheels and the design of the function elements for the operating fluid circuit. The power characteristic curves for the fill-controlled couplings match that of the constant-fill couplings, as the graduation of the profile diameter and several design limits for both designs are the same. The power of the driven machine and the rated speed of the drive motor also mainly determine the coupling size in this case. The application and use conditions together form the main factors for establishing the control principle, the component scope, the execution of the operating fluid supply and the control and monitoring equipment.

Fig. 51 describes two start-up processes for a belt conveyor – a typical application for fill-controlled couplings. The acceleration tension level and duration have a direct effect on its acquisition costs and service life. The gradual build-up of torque over time and the tight control of torque levels are therefore very important design criteria for conveying systems.

The pump impeller and turbine wheel are the same as those in the variable-speed coupling series. They produce a diversified set of secondary characteristic curves. With suitable control or regulation, the start-up of the belt conveyor is ensured within tightly pre-defined limits dependent on load.

The use of a fill-controlled fluid coupling in the drive of a belt conveyor, like the example described in section 4.2.1, brings additional noteworthy advantages for the entire system: The motor run-up and the start-up of the conveyor are independent of each other from a time perspective. Torque peaks resulting from switching on the asynchronous motor – whose amplitudes can reach 4 to 5 times the rated torque – do not affect the entire system. Even high-voltage motors with low start-up torque (service factor below 10) run up safely thanks to the load decoupling characteristic of the fluid coupling. With multi-motor drives and weak power supplies, it is possible to have time-delayed activation of the individual motors to protect the power supply with no further action required. The couplings remain empty until all motors are activated. The torque build-up – and thus the tensile force in the belt – can occur gently and in a controlled manner in line with the quality of the belt. The torque limitation is possible within tight limits, dependent on the load.

Another typical use for fill-controlled couplings is within armored face conveyor drives in underground coal mining operations. The system properties of the hydrodynamic power transmission described above apply there in the same way.

5.3 Materials

The basic parameters from the hydrodynamic model relationships are torque, speed and the properties of the operating fluid. They also extensively influence the material selection for the main components of the coupling. Fig. 52 shows the most important criteria selecting the material.

It is preferable to use cast aluminum alloy parts for the main components of constant-fill couplings with medium stress levels and for smaller series. Alloys of this kind have a favorable strength to density ratio and also offer low weight and good processing capability. For medium series, the most economic production method is more likely to determine the material selection. For large series, an automated steel plate lightweight construction is usually the most cost-effective.

Cast steel or quenched and tempered steel with electrochemically or mechanically processed flow channels is a good material selection if there is high stress at high speeds.

In marine propulsion, it is generally the application that determines the selected material. Typically these are smaller batch sizes, usually with larger dimensions and corresponding stresses. For example, aluminum alloys are antimagnetic; spheroidal cast iron allows a higher degree of elongation when stressed by shock; steel plates enable cost-effective vane welding; and copper-bronze has good resistance to corrosion.

Material selection	
Function	Profile geometry, vane format, flow channels, density, mass
Stress factors	Centrifugal forces, fluid pressure, torque, forces from change in temperature
Manufacture	Costs for raw parts, processing, devices and models
Process suitability	Maintenance costs, corrosion resistance, abrasion resistance (for a contaminated operating medium), spark formation (in potentially explosive areas)

Fig. 52: Criteria for selecting the material used for main coupling components

5.4 Operating fluids

In hydrodynamic couplings, a circumferential fluid flow transfers the power from the pump to the turbine. The operating fluid is therefore of great significance; it is an important design element for the whole system. The density and viscosity of the fluid are of primary importance. Another key task is to take in the heat resulting from the power loss and then transfer it to the coupling components.

The properties that the operating fluid must fulfill in practical use are numerous and depend on the design of the coupling and its integration into the system as a whole. The operating fluid is selected on the basis of the parameter requirements for the power transmission, the material compatibility, the application range and the process capability. The minimum lubricant capability for antifriction bearings and the compatibility with sealing materials are dependent on the design.

Fig. 53: Requirements chart for operating fluids in fluid couplings;
Requirements for HFD-U and HDS only apply to tested types

5.4.1 Standard operating fluids

HLP (mineral-oil based) hydraulic oils within the ISO VG 32 viscosity class are the standard operating fluids used for fluid couplings. The details in design documentation, especially characteristic curve representations, usually refer to these operating fluids.

The viscosity is significant to the power transmission because it has a considerable effect in determining the friction in the flow channel. The lower the viscosity, the lower the speed losses of the circumferential mass flow in the flow channel. The influence of the viscosity on the characteristic curve course is usually negligible when using standard operating fluids in the authorized temperature range.

In special cases, e.g. use in low temperatures, it is possible to adapt the viscosity class. A check of the influence on operating behavior (characteristic curve) is required in such circumstances.

5.4.2 Special operating fluids

Mineral oil was often not an option as an operating fluid for primary applications in the underground mining industry or for use in water protection areas. This required the approval of non-flammable or flame-resistant and environmentally friendly operating fluids – for both constant-fill couplings and for fill-controlled couplings.

Water or HFA fluids (oil in water emulsions) fulfill the requirements of the underground use. Various disadvantages limit the use predominantly to this application area. The low service temperature and the cavitation tendency limit the power spectrum of the coupling.

Fig. 54 shows design measures that permit the use of water or HFA fluid in a fluid coupling. Specifically, these are:

- Shaft seal rings to shield the bearing chambers
- Lubricating the bearings with low-viscosity grease (life-long grease filling)
- Rust-proof steels
- Hard anodized, oxidized aluminum cast parts
- Low-temperature fusible plugs

The further development of flame-resistant HFD-U fluids (water-free, synthetic fluids) depicts a friendlier image. They do not require additional design measures for the fluid coupling. Parallel to this development is the introduction of biodegradable operating fluids based on synthetic ester (HEES fluid). Both operating fluids have successfully performed in bench tests and are already in use.

5.4.3 Special design aspects of constant-fill couplings

One design feature must be considered in conjunction with operating fluids for fluid couplings with constant fill: The couplings are sealed to the outside, and the exchange of gases or fluids with the environment is not easily possible. Measures to limit the thermal inner pressure must therefore be implemented:

The design arrangement of the fill opening is designed so that the maximum fill level is 80 %. The design of the coupling surface ensures the conductance of the slip heat that builds up during the start-up process and in nominal operation. A limitation of the start-up frequency to reduce thermal stress may be necessary.

In addition, installed thermal limit switches enable targeted reactions to excessive temperature – before the thermal stress boundary is reached. Installing an additional thermal measuring unit is especially advantageous, since it enables not only temperature monitoring but also optimal process control (for example at the load limit).

All constant-fill couplings also have fusible plugs that release an opening if the thermal stress limit is exceeded. The operating fluid exits from this opening and the traction is interrupted.

Fig. 54: Fluid coupling for water or HFA fluid as an operating fluid. The design changes apply analogously for fill-controlled couplings.
